Robust and Effective Component-based Banknote Recognition for the Blind

Faiz M. Hasanuzzaman*, Xiaodong Yang*, and YingLi Tian, Senior Member, IEEE

Abstract—We develop a novel camera-based computer vision technology to automatically recognize banknotes for assisting visually impaired people. Our banknote recognition system is robust and effective with the following features: 1) high accuracy: high true recognition rate and low false recognition rate, 2) robustness: handles a variety of currency designs and bills in various conditions, 3) high efficiency: recognizes banknotes quickly, and 4) ease of use: helps blind users to aim the target for image capture. To make the system robust to a variety of conditions including occlusion, rotation, scaling, cluttered background, illumination change, viewpoint variation, and worn or wrinkled bills, we propose a component-based framework by using Speeded Up Robust Features (SURF). Furthermore, we employ the spatial relationship of matched SURF features to detect if there is a bill in the camera view. This process largely alleviates false recognition and can guide the user to correctly aim at the bill to be recognized. The robustness and generalizability of the proposed system is evaluated on a dataset including both positive images (with U.S. banknotes) and negative images (no U.S. banknotes) collected under a variety of conditions. The proposed algorithm, achieves 100% true recognition rate and 0% false recognition rate. Our banknote recognition system is also tested by blind users.

Index Terms—banknote recognition, blind and visually impaired, component-based, computer vision, SURF

I. INTRODUCTION

World Health Organization (WHO) approximates that there were 161 million visually impaired people around the world in 2002, about 2.6% of the total population. Among these statistics, 124 million had low vision and 37 million were blind [15]. Visually impaired people face a number of challenges when interacting with the environments because so much information is encoded visually in daily life. One specific difficulty that a blind person would encounter is to know the value of the currency or bill he or she is holding. Currently, printed denominations of U.S. currency are $1, $2, $5, $10, $20, $50, and $100. With a few recent exceptions all of the banknotes are identical in size and color, and inaccessible to people who are blind or significantly visually impaired. Although a federal judge has ruled that the U.S. Treasury Department is violating the law by failing to design and issue currency that is readily distinguishable to blind and visually impaired people, in November 2006, the Treasury Department argued that any change would be costly, with estimates ranging from $75 million for equipment and $9 million in annual expenses to punch holes, to $178 million in one-time charges and $50 million in annual expenses to print different-size bills [20]. Some latest redesigned money has been issued with an enlarged color number for visually impaired people. However, it may take years to issue bills with additional blind-friendly changes.

According to the American Foundation for the Blind [1], one way that a blind person can identify paper currency is to fold each denomination in different ways. The recommendation for folding some currency is to fold five-dollar bills lengthwise, ten-dollar bills widthwise, twenty-dollar bills are folded twice and one-dollar bills may remain unfolded and put into a wallet. Although the idea of folding the bills is good, it needs others’ help to organize bills. Recent advances in theories, sensors, and embedded computing hold the promise to enable computer vision technique to address their needs. Although a number of studies on camera-based bill recognition have been published in literatures [3, 9, 10, 13, 16-18, 31-33], some of them are restricted to specific and standard environment. For example, the whole bill must be visible without occlusion, wrinkles, etc. Furthermore, none of the existing methods provides the analysis of recognition of negative images (i.e. images do not contain banknotes) and aiming guidance for blind users. An automatic banknote recognition system for blind people should be able to recognize banknotes in a wide variety of real world environments, such as occlusions, cluttered background, varied illumination, different viewpoints, and worn or wrinkled bills, as well as to provide the feedback of aiming guidance.

The extraction of sufficient, stable, and distinctive monetary features is significant for accuracy and robustness of a banknote recognition algorithm. Recent developments of interest points detectors and descriptors in computer vision such as Scale Invariant Feature Transform (SIFT) [19] and Speeded Up Robust Feature (SURF) [2] enable the extraction of sufficient, stable, and distinctive recognition of monetary characteristics by using local image features. The
environments for the blind: recognition of banknotes in a wide variety of real world conditions in real world environments. Fig. 1 shows our system diagram. First, monetary features of each query image are extracted by SURF. These features are then matched with the pre-computed SURF features of reference regions of the ground truth image in each banknote category. The numbers of matched features are compared with automatic thresholds of each reference region to determine the banknote category. Furthermore, the spatial relationship of matched features is employed to avoid false recognition with negative images and provide aiming guidance to blind users for bill image capture. Then the system outputs the recognition result.

**Fig. 1:** System diagram of the proposed banknote recognition for the blind.

An earlier version of this paper can be found in [10]. Compared to our previous work, there are three major extensions that merit being highlighted: 1) the previous work manually set the matching thresholds for each region. The automatic thresholding method proposed in this paper can learn all the thresholds from training images so that the proposed method can be easily extended to recognize banknotes from different countries (Section III-C); 2) the previous work was not able to handle negative images (i.e. query images containing no bills). In this paper, we propose a spatial clustering method to detect if there is a bill in the camera view and further use the detection result to guide the blind users to correctly aim the target (Section III-D). This process significantly reduces false recognition rate; and 3) we enlarge the evaluation dataset and add more experimental results and demonstrate the efficiency and robustness of the proposed work. In addition, the proposed system is evaluated by 9 blind users. Overall, the work introduced in this paper offers the following main contributions to robust and efficient recognition of banknotes in a wide variety of real world environments for the blind:

- We propose a component-based framework to handle a variety of conditions including occlusion, cluttered background, viewpoint variation, and worn or wrinkled bills due to the following reasons: 1) components retain more discriminative information for banknote categories, while other parts of the banknotes are similar across different categories; 2) components vary much less than the global pattern under the geometric transform; and 3) the component-based model is insensitive to partial occlusions and background clutter.

- We propose a new automatic method to obtain matching threshold (Section III-C). This benefits the extension of our system to recognize banknotes of different countries.

- We employ SURF features in the banknote recognition system to handle rotation, scaling, and illumination changes due to their robustness for geometric and photometric variations, and great speed improvement.

- We propose a new schema by employing the spatial information of matched SURF features to avoid false recognitions (i.e. recognize negative images as banknotes).

- To solve the aiming problem of blind users, we further provide audio guidance to the user if there is no banknote in the camera view based on the recognition results.

- The proposed banknote recognition system is evaluated by 9 blind subjects.

## II. RELATED WORK

In the last 50 years there have been many efforts to develop electronic aids to improve quality of life and the safety of individuals with special needs [4, 6, 21, 22, 29, 30, 34-36, 38, 39, 45-47]. Several techniques have been developed to identify banknotes from camera captured images for helping blind or visually impaired people. Lee et al. [18] proposed a method to extract features from specific parts of Euro banknotes representing the same color. In order to recognize banknotes, they used two key properties of banknotes: direction (front, rotated front, back, and rotated back) and face value (5 10, 20, 50, 100, 200 and 500). They trained five neural networks for insert direction detection and face value classification. The results showed a high recognition rate (about 98.5%) and a low training period. Forsini et al. also presented a neural network based bill recognition and verification method [5]. Kosaka and Omatu proposed the learning vector quantization (LVQ) method to recognize 8 kinds of Italian Liras [16, 17]. Most banknote recognition methods employed neural network techniques for classification [13, 16-18, 31-33].

Reiff and Sincak [27] used SIFT detector and descriptors to classify Slovak banknotes in a well-controlled environment. Symmetrical masks have been used by Vila et al. for considering specific signs in a paper currency [37]. In their method, the summation of non-masked pixel values in each
banknote is computed and fed to a neural network. This method considers images of both the front and back of the paper currency, but only the front image is used for recognition. In the approach of [40], the patterns of an edge on a banknote are used for recognition and the image of a banknote is vertically divided into a number of equal small parts. Then the number of pixels associated to edges detected in each part are counted and fed to a three layer back propagation neural network for recognition. Hassanpour et al. [9] proposed a Hidden Markov Model (HMM) model based method. By employing HMM, the texture characteristics of paper currencies are modeled as random processes and can be extended for distinguishing paper currency from different countries. In the above methods, the whole bill must be visible without occlusion, wrinkles, etc. Neither of these methods analyzes the false recognition nor considers the aiming problem of blind users.

As shown in Fig. 2, a portable bill recognition product in the market is called “Note Teller 2,” which is manufactured by BRYTECH of Canada [26]. The bill must be inserted in a slot on the top of this device. Based on the evaluation of AFB TECH [11], the overall identification accuracy of “Note Teller 2” is about 80% and it has difficulty in identifying worn or wrinkled bills. Compared to the constrained recognition environment of “Note Teller 2”, our system enables banknote recognition in an open environment, i.e. blind users only need to hold a bill and take an image of the bill (e.g. by a wearable camera on sunglasses or a cell phone camera).

Similar to banknote recognition, systems for coin recognition have also been proposed. Huber et al. [41] applied a multistage approach to coin recognition. In this work, segmentation and rotational angle estimation were used to achieve translation and rotation invariance. Principle Components Analysis (PCA) was further employed to tackle illumination change. Shen et al. [42] proposed to extract local texture features by Gabor wavelets and Local Binary Pattern (LBP) to represent coin images. Because of experimental settings and properties of coins, the above coin systems did not take into account of the conditions such as partial occlusion, cluttered background, scaling change, and wrinkling, which, however, are quite common in the scenario of banknote recognition for the blind people.

III. PROPOSED METHOD

A. Component-based Framework for Banknote Recognition

The proposed banknote recognition algorithm is based on a component-based model. It has four main advantages over the global model: 1) the class specific information is not evenly distributed on the banknote. Some regions cover more obvious class specific features, while other regions are relatively similar across different classes. It will be more effective to use those more class specific components in the recognition of banknotes. 2) A component-based model is able to focus on local and stable parts, which vary much less than the pattern of an entire banknote under the geometric and photometric changes. 3) Local image features generated from components are much less than that from the entire image. This helps to speed up the matching process and reduce memory requirement. 4) A component-based model is more robust in handling partial occlusions. It is empirically impossible to take account of all conditions which cover the spectrum of possible variations that can result from occlusions. In the component-based model, individual components are detected by their corresponding detectors. Partial occlusions only affect the
outputs of a portion of component detectors. As long as a certain amount of components are detected, the whole banknote is still able to be recognized.

**Component Generation:** In our banknote recognition system, ground truth images for both front side and back side of each category banknote are first collected under optimal conditions. Fig. 3 shows the reference banknote images of front and back sides of $1, $2, $5, $10, $20, $50, and $100 U.S. bills. The marked regions in red are the components chosen as reference regions for each category. For example, in the $5 bill the distinguish specific information in the front side is the number “5”, the word “FIVE” and the face picture of Lincoln. Similarly on the back side of the $5 bill, the number “5”, the word “FIVE”, and Lincoln Memorial are the most discriminative regions. Note that the golden number “10” on the right-bottom corner of the front side in $10 bill (also for the golden numbers “20” and “50” in $20 and $50 bills) is not taken into account because the matching of local image features within this region does not perform well. The same principal applies to all the other bills on both front and back sides.

In our system, a total of 14 images of seven categories of bills ($1, $2, $5, $10, $20, $50, and $100) with front and back sides are taken as ground truth images. The resolution of all bills ($1, $2, $5, $10, $20, $50, and $100 U.S. bills). The marked regions in red are the components chosen as reference regions for each category. For example, in the $5 bill the distinguish specific information in the front side is the number “5”, the word “FIVE” and the face picture of Lincoln. Similarly on the back side of the $5 bill, the number “5”, the word “FIVE”, and Lincoln Memorial are the most discriminative regions. Note that the golden number “10” on the right-bottom corner of the front side in $10 bill (also for the golden numbers “20” and “50” in $20 and $50 bills) is not taken into account because the matching of local image features within this region does not perform well. The same principal applies to all the other bills on both front and back sides.

In our system, a total of 14 images of seven categories of bills ($1, $2, $5, $10, $20, $50, and $100) with front and back sides are taken as ground truth images. The resolution of all the ground truth banknote images is 835×354. The size of each bill is 8×3 pixels. The resolution of all banknotes with front and back sides. The resolution of all bills is 8×3 pixels. The resolution of all banknotes with front and back sides.

The detection and representation of image features are essential to many applications, such as image retrieval and recognition of object, texture, and scene categories, as they are more resistant to partial occlusion, background clutter, and viewpoint changes [14, 28]. This has motivated the development of several scale- and rotation-invariant local image detectors and descriptors. Generally, detectors localize interest points with stable regions in a scale-space; descriptors build the representation of the support regions provided by detectors. The performance evaluations [2] of local image features observed SURF was comparable with and often better than state-of-the-art systems, such as SIFT [19] and GLOH [24]. Furthermore, SURF can be computed and compared much faster, which is desirable in real-time applications. We choose SURF as the detection and representation of local image features based on the following reasons: 1) Banknote images could be taken under the circumstances of rotation and scaling change. Interest points with support regions detected by SURF are robust to rotation and scaling change. 2) Descriptors associated with support regions are distinctive and compact for feature matching. 3) The low computational cost of SURF facilitates fast interest point localization and matching. In order to make this article more self-contained, we briefly discuss the construction process of SURF in this section.

**B1. Interest Points Detection and Description**

SURF is a combination of detector and descriptor which are computationally effective. The significant speed improvement of SURF detector is due to efficient use of integral images. SURF detector is based on Hessian matrix [2] because of its good performance in detecting blob-like structures. The Hessian matrix is further approximated by using box filters to substitute for discretized second order Gaussian derivatives. This enables the fast evaluation of second order Gaussian partial derivatives by taking advantage of integral images. Thanks to the use of box filters and integral images, SURF detector builds the scale space by up-scaling the sizes of box filters rather than iteratively reducing the image size. The location of interest points in the image and over scale space is finally determined by the maximum determinant of approximated Hessian matrix in a 3×3×3 neighborhood. In order to achieve rotation-invariance, SURF descriptor first identifies the dominant orientation of a support region by the Gaussian weighted Haar wavelet responses. The support region is then oriented along its dominant orientation. The support region is quantized into 4×4 Cartesian location bins. Each location bin is further divided into 5×5 sample points. Haar wavelet responses at each sample point are computed including horizontal response $d_x$ and vertical response $d_y$. The responses are further weighted by a Gaussian window to be robust to geometric disturbance and localization error. The sum $d_x$, $d_y$, $|d_x|$, and $|d_y|$ over 5×5 sample points constitute the feature vector for each location bin. Concatenating the feature vectors of 4×4 location bins generates the SURF descriptor with 64 dimensions. The descriptor is then normalized to a unit vector to be contrast invariant.

**B2. SURF Evaluation on Banknotes**

In order to validate the repeatability, distinctiveness, and robustness of local image features extracted by SURF in banknote recognition, we evaluate the matching performance between the reference regions and banknote images taken under a variety of circumstances. We use 140 banknote images containing 20 images for each category of U.S. bill ($1, $2, $5, $10, $20, $50, and $100) and 50 negative images (see Fig. 7 for image examples). The banknote images are collected from a wide variety of conditions, such as occlusion, rotation, changes of scaling, illumination and viewpoints. The negative images include both indoor and outdoor scenes. The reference regions of 14 ground truth images of seven categories of bills are used to match with training images based on SURF. If the distance between SURF descriptors of two interest points is below a certain threshold, the two interest points are matched.

The matching results are described in the confusion matrix in Table 1. Each row in Table 1 corresponds to the average matching results for banknote images of each category. Element $(i,j)$ corresponds to the average number of matched points between banknote images of category $i$ and reference regions of category $j$. Each row is further normalized by the maximum number of matching points in this row. As we see, the best matching cases all occur at the diagonal elements of
the confusion matrix. In addition, off-diagonal elements are much smaller than 1. This demonstrates SURF descriptors are of great distinctiveness to distinguish local image features from different banknote categories and backgrounds. Therefore, it can be concluded from this confusion matrix that the SURF is able to represent and match local image features of banknotes accurately even under a variety of geometric and photometric variations.

**C. Recognizing Banknotes by Automatic Feature Matching Thresholding**

As shown in Fig. 1, given a query image, SURF first detects the interest points and generates corresponding descriptors. The pre-computed SURF descriptors of reference regions in each category are then used to match with the extracted descriptors of the query image. The number of matched points between the query image and reference regions of different categories determines the reference region matching results. If $N_i^j$, the number of matched points between the query image and $R_i^j$ (i.e., the reference region-$j$ in category-$i$) is larger than $T_i^j$, the automatic threshold of $R_i^j$, then $R_i^j$, the reference region-$j$ in category-$i$, is matched to this query image.

Here we propose an automatic thresholding method to obtain $T_i^j$ for each reference region by the histogram of the matched points numbers between reference regions and images in our training dataset. The training set includes 140 positive images with 20 images in each category and 50 negative images. For each $R_i^j$, its pre-computed SURF descriptors are matched with extracted descriptors from training images of category-$i$ and the rest training images, respectively. The matching results are used to build the matching histogram as shown in Fig. 4. The red distribution is the histogram of matched point numbers between $R_i^j$ and training images of category-$i$. Similarly for the blue distribution, it describes the matching result between $R_i^j$ and the rest images in the training set. The training images in category-$i$ contain $R_i^j$, while the rest images in the training set do not have such a region. So the average number of matched points of the red histogram is larger than that of the blue histogram. Due to partial occlusions, geometric and photometric variations of the images, the distributions of the matched points numbers present variances in both cases. The number of matched points corresponding to the intersection point between the two histograms is used as the automatic threshold $T_i^j$ for $R_i^j$. The automatic thresholds of all the reference regions in different categories can be generated this way.

To recognize the category of a query image, all of the reference regions matched to the query image are retained. In the next step, the number of matched reference regions in each category is employed to determine the recognition category. The query image is recognized as category-$i$ if this image has the maximum number of matched reference regions with category-$i$, and this number is not less than 2. From our recognition experiments, two matched reference regions are flexible in handling partial occlusions and are confident in recognizing the banknote category as well. If more than one category satisfies the above recognition rule, the total number of matched points in all matched reference regions is used to determine the final recognition category which maximizes the total number.

**D. Spatial Clustering of Matching Features to Handle Negative Images and Aiming Problem of Blind Users**

We discussed the recognition of a query image of a bill in above sections. However, aiming problem is a common issue for blind users and will lead to many query images without any bill in the camera view (i.e., negative images). For some negative images with highly cluttered background, the number of matched points and the number of matched reference regions might pass the matching features thresholding rules (Section C). In this case, a negative image will also be recognized as a certain banknote category, which is obviously a false recognition. Therefore, in order to assist the blind users in aiming at a banknote and to avoid false negative recognitions, we employ the spatial relationship between matched points to validate if a query image is really a bill. As shown in Fig. 5, the matched points matching to the same
reference region are displayed in the same color. In the true recognition shown in Fig. 5(a), matched points with the same color tend to cluster together as the spatial constraint of every matched region. While for the false case shown in Fig. 5(b), matched points with the same color almost randomly distribute on the entire image. The different spatial relationships of matched points can be used to distinguish the positive images containing banknotes from the negative images.

![Fig. 5: Spatial relationship between matched points. Points matched to the same reference region are in the same color. (a) In the positive image, the points in the same color tend to group in the same cluster for the positive image. (b) In the negative image, the matched points almost randomly distribute on the image for the negative image.](image)

We apply the k-means clustering [12] to analyze the spatial relationship between matched points. The aim of k-means clustering is to partition \( n \) matched points into \( k \) clusters in which each point belongs to the cluster with the nearest distance. Given a set of matched points \( \{x_1, x_2, \ldots, x_n\} \), where each point is a 2-dimensional position vector, k-means clustering partitions the \( n \) points into \( k \) sets \( (k \leq n) \): \( S = \{S_1, S_2, \ldots, S_k\} \) so as to minimize the within cluster sum of distances:

\[
\arg \min_S \sum_{i=1}^{k} \sum_{x_j \in S_i} ||x_j - \mu_i||^2
\]

(1)

where \( \mu_i \) is the centroid of \( S_i \), i.e. the mean of points in \( S_i \). In the experiments, we set \( k \) as the number of the matching regions. For example, if there are four matching regions, then \( k = 4 \). The results of k-means clustering are presented with purity values. Purity is the number of dominant points in a cluster with respect to the total number of points in this cluster. As shown in Fig. 6, in the cluster set \( S_i \), \(#P_a\) the number of matched points with reference region-\( a \) is larger than those from other reference regions, i.e. \(#P_b\) and \(#P_c\). Thus the points matched to reference region-\( a \) are dominant points. The purity of this cluster set is the ratio between \(#P_a\) and the sum of \(#P_a\), \(#P_b\), and \(#P_c\). As the matched points of positive images tend to cluster much more than the case in negative images, the purity values of each cluster of positive images are therefore much larger than that of negative images. From our empirical observation, if the purity value of any cluster set is less than 0.16, then this query image is determined as a negative image.

IV. BANKNOTE RECOGNITION SYSTEM DEVELOPMENT

Taking all the components in Fig. 1, we form the component-based banknote recognition system. The system includes three main components: (a) sensors including a camera to capture a query image, a microphone for speech command input, and speakers (or Bluetooth, earphone) for audio output; (b) data capture and analysis to perform command control and banknote recognition by using a wearable computer (e.g. a mini-computer, a PDA, or a mobile phone); and (c) audio outputs to provide the banknote recognition result.

The implementation procedure of our proposed banknote recognition algorithm is summarized in Table 2. The SURF is first applied to extract the descriptors \( D \) of the marked reference regions \( R \) in each banknote category \( C \). The extracted SURF descriptors are stored in a database for the following matching. Given a query image, the system employs SURF to extract the descriptors \( D \), which are then used to match with pre-computed SURF descriptors stored in the database. If the number of matched features with reference region-\( j \) in category-\( i \) is larger than its associated automatic threshold \( T_{ij} \), this reference region is matched to the query image. For each category \( C \), if the number of matched regions \( M_i \) is not less than 2, \( C_i \) is added in the candidate. If no candidate after the matching features thresholding, this means the query image is a negative image. So the output will show no bill is detected in the query image. If more than one category in the candidate, the total number of matched features of all matched reference regions is used to determine the optimal category, which maximizes this total number. Now only one category presents in the candidate.

In order to avoid false positive recognition, we employ k-means clustering to the matched points and obtain a set of clusters and corresponding purity values. Since matched points tend to spread out on the entire negative image, the purity values of cluster sets in negative cases are very low. Therefore, if any purity value of cluster sets is not large than 0.16, this query image is also determined to be negative.
image. Accordingly, the output displays no bill detected. Otherwise, the query image is recognized as a true positive case and the output returns the banknote value of the query image.

</table>

The performance of the proposed banknote recognition algorithm has been evaluated by two datasets where one is collected by developers and the other one is collected by 9 blind subjects. This section focuses on the system evaluation by using the dataset collected by developers which includes both positive banknote images and negative background images. The positive set contains total 280 images with 40 images covering both front side and back side for each category of bill ($\$1$, $\$2$, $\$5$, $\$10$, $\$20$, $\$50$, and $\$100$). Note that the proposed system recognizes one banknote each time (i.e. there are no multiple banknotes present in the same image.) The negative set contains 100 background images without any banknote in each image. These images are selected from a wide variety of conditions to approximate the environment of real world application. Experimental results validate the effectiveness and robustness of our component-based banknote recognition algorithm using SURF.

Fig. 7: Training and testing data set of banknote images taken under different conditions and negative images: 1st row (partial occlusion), 2nd row (cluttered background), 3rd row (rotation), 4th row (scaling change), 5th row (illumination change), 6th row (wrinkling), 7th row (negative images).

### A. Experiment Setup

The banknote dataset is collected from a wide variety of circumstances. Fig. 7 demonstrates four sample images from each condition. The samples from the 1st row to the 6th row correspond to the conditions of partial occlusion, cluttered background, rotation, scaling, lighting change, and wrinkling. The 7th row displays four sample images of negative images. In some cases some of the conditions are combined into one condition such as scaling and cluttering. The dataset will be released to public at our website. In real world applications, the user may take the banknote in his/her hand which can correspond to the “both occluded and wrinkled” case. The user may also take a negative image with no bill due to the aiming problem. The banknote dataset presented in our experiment is more challenging than that from other banknote recognition papers. For example, the dataset in [32] was collected by using a scanner to scan the bills which were taken under restricted or standard conditions. So our dataset generalizing the conditions of taking banknote images is more challenging and more closely approximates the real world environment. In the experiments, we randomly select 140 positive images and 50 negative images as training set used to obtain the automatic thresholds for reference regions. The remaining positive and
negative images are used as a testing set.

B. Experimental Results and Discussion

Each category of bill images cover all of the conditions of partial occlusion, cluttered background, rotation, scaling change and illumination change, as well as wrinkling. In the recognition experiments evaluated in our testing dataset, the proposed algorithm achieves 100% true recognition accuracy for all seven categories and 0% false recognition rate. Table 3 shows the evaluation results for each category. The experimental results have shown the effectiveness of the monetary features extracted by SURF and our component-based framework for banknote recognition.

![Table 3: Recognition Results for Seven Categories of Banknotes.](image)

Although our algorithm is evaluated in a more challenging dataset, our algorithm achieves much better recognition results and outperforms the existing banknote recognition algorithms. For instance, the average recognition rate of the algorithm [27] based on SIFT is 76%. Some neural network based banknote recognition systems achieved recognition rate no large than 95% [16, 17, 31-33]. Because of specific design, the testing images in these references were captured in highly constrained environments, such as a transaction machine or a specific sensor system which are not portable [5, 31, 33]. Therefore, the variations of testing images evaluated in these systems are quite limited. Their images only presented rotation and translation changes, and sometimes might be worn out or with defected corners. Compared to these references, our system is designed as a portable device for blind users in daily life by using a wearable camera or a camera on a cell phone, images are captured in open environments with a wide variety conditions including partial occlusion, highly cluttered background, rotation, scaling change, illumination change, as well as wrinkling. In other words, the variety conditions presented in our dataset fully cover the ones in others. While our system is evaluated on much more challenging images, our recognition result is still better than other work evaluated on images collected in much simpler conditions.

The success of our proposed algorithm mainly lies in: 1) the scale- and rotation-invariant detector and distinctive descriptor provided by SURF is robust to handle the image rotation, scaling change and illumination change; 2) our component-based framework generates more category-specific information which is more discriminative to distinguish a query image from cluttered background and effective to deal with partial occlusions; 3) the spatial clustering approach is effective to filter out negative images by using the spatial relationship between matched points.

However, further experiments show that extremely large scaling change will affect the recognition results. This is because SURF descriptor is resistant to scaling change in a certain range. When the resolution of a query image is very low, the system cannot detect considerable points in bills. But in real application, it is reasonable to assume a blind person takes the bill in the range without extreme scaling change.

The computational cost of the entire recognition algorithm includes extracting SURF features from a query image, matching them with pre-computed features of all the reference regions, k-means clustering of matched points, and displaying the recognition output. The average speed of the algorithm on a testing image at the resolution of 1024x768 pixels is about 2.5 seconds on a computer with 3GHz CPU.

VI. SYSTEM TESTING BY BLIND USERS

The proposed banknote recognition system was further tested by 9 blind subjects including 4 men and 5 women with ages ranging from 36 to 72 years old. The images are captured by a camera mounted on a pair of sunglasses with the blind user hold the bill to be recognized as shown in Fig. 8. The dataset collected by blind subjects includes total 579 positive images: 68 images of $1, 44 images of $2, 73 images of $5, 129 images of $10, 71 images of $20, 129 images of $50, and 65 images of $100. As shown in Fig. 9, the images collected by blind subjects present a large variation of viewpoint, rotation, occlusion, wrinkling, as well as cluttered background. Our algorithm correctly recognizes all the 579 images and achieves 100% recognition rate.

![Fig. 8: Evaluation of proposed system by blind subjects. The bill to be recognized is held by hands and image captured by a camera mounted on a pair of sunglasses.](image)

From the system evaluation by blind subjects, it is observed that the proposed method cannot recognize banknote images in the following two conditions: 1) banknote images taken under severe motion blur (e.g. the first two images of the 4th row in Fig. 9); 2) banknote with only one or none component visible (e.g. the third image of the 4th row in Fig. 9). For highly blurred images, the SURF is not able to extract accurate local image features that are the basis for the flowing feature matching. To balance the reliability of recognition and the
ability to handle occlusion, the system requires at least two matched regions, as mentioned in Sec. III-C. For highly occluded images, they cannot provide enough visible banknote components. However, our system treats images in both cases as negative recognitions and sends feedback to blind subjects to guide users to adjust their image capture. Since blind users can be collaborative, they will be able to capture good quality images by system feedback and a simple user training process.

VII. CONCLUSION AND FUTURE WORK

In this paper, we have proposed a component-based framework for banknote recognition using SURF. Patches with descriptive features for each banknote category are selected as reference regions for matching with query images. The proposed algorithm has been evaluated by dataset to a variety of conditions including occlusion, rotation, scaling, cluttered background, illumination change, viewpoint variation, and worn or wrinkled bills, and further by blind subjects. Our approach achieves 100% true recognition rate and 0% negative recognition rate.

In the future work, we will address the issue of motion blur in two perspectives: 1) integrate deblurring techniques [43, 44] into our system; 2) provide a simple training process to familiarize blind users with the device to reduce motion blur. Our future work will also focus on evaluating the proposed system to recognize banknotes of different countries and transferring the method to mobile phones.

ACKNOWLEDGMENTS

The authors thank Dr. Aries Arditi for recruiting blind subjects to conduct the algorithm and system evaluation. The authors also would like to thank the anonymous reviewers for their constructive comments and insightful suggestions that improved the quality of this manuscript.
